Overview

Ordinary differential equations

An equation containing a function of one independent variable and its derivatives, in contrast to a *partial differential equation*, which contains derivatives with respect to more independent variables.

Main question

How to solve

$$\frac{dy}{dx} = f(y(x), x) \quad \text{with} \quad y(x=0) = y_0$$

accurately and efficiently?

What is an ODE?

- Algebraic equation:

$$f(y(x), x) = 0 \quad \text{e.g. } -\ln(K_{eq}) = (1 - \zeta)$$

- First order ODE:

$$f\left(\frac{dy}{dx}(x), y(x), x\right) = 0 \quad \text{e.g. } \frac{dc}{dt} = -kc^n$$

- Second order ODE:

$$f\left(\frac{d^2y}{dx^2}(x), \frac{dy}{dx}(x), y(x), x\right) = 0 \quad \text{e.g. } \mathcal{D} \frac{d^2c}{dx^2} = -\frac{kc}{1 + Kc}$$

About second order ODEs

Very often a second order ODE can be rewritten into a system of first order ODEs (whether it is handy depends on the boundary conditions!)

More general

Consider the second order ODE:

$$\frac{d^2y}{dx^2} + q(x) \frac{dy}{dx} = r(x)$$

Now define and solve using z as a new variable:

$$\frac{dy}{dx} = z(x)$$

$$\frac{dz}{dx} = r(x) - q(x)z(x)$$

Importance of boundary conditions

The nature of boundary conditions determines the appropriate numerical method. Classification into 2 main categories:

- *Initial value problems (IVP)*

We know the values of all y_i at some starting position x_s , and it is desired to find the values of y_i at some final point x_f .

- *Boundary value problems (BVP)*

Boundary conditions are specified at more than one x . Typically, some of the BC are specified at x_s and the remainder at x_f .

Overview

Initial value problems:

- Explicit methods
 - First order: forward Euler
 - Second order: improved Euler (RK2)
 - Fourth order: Runge-Kutta 4 (RK4)
 - Step size control
- Implicit methods
 - First order: backward Euler
 - Second order: midpoint rule

Boundary value problems

- Shooting method

Euler's method

Consider the following single initial value problem:

$$\frac{dc}{dt} = f(c(t), t) \quad \text{with} \quad c(t=0) = c_0 \quad (\text{initial value problem})$$

Easiest solution algorithm: Euler's method, derived here via Taylor series expansion:

$$c(t_0 + \Delta t) \approx c(t_0) + \left. \frac{dc}{dt} \right|_{t_0} \Delta t + \frac{1}{2} \left. \frac{d^2c}{dt^2} \right|_{t_0} (\Delta t)^2 + \mathcal{O}(\Delta t^3)$$

Neglect terms with higher order than two: $\left. \frac{dc}{dt} \right|_{t_0} = \frac{c(t_0 + \Delta t) - c(t_0)}{\Delta t}$ Substitution:

$$\frac{c(t_0 + \Delta t) - c(t_0)}{\Delta t} = f(c_0, t_0) \Rightarrow c(t_0 + \Delta t) = c(t_0) + \Delta t f(c_0, t_0)$$

Euler's method: graphical example

$$\frac{c(t_0 + \Delta t) - c(t_0)}{\Delta t} = f(c_0, t_0) \Rightarrow c(t_0 + \Delta t) = c(t_0) + \Delta t f(c_0, t_0)$$

Euler's method - solution method

Start with $t = t_0$, $c = c_0$, then calculate at discrete points in time:
 $c(t_1 = t_0 + \Delta t) = c(t_0) + \Delta t f(c_0, t_0)$.

Pseudo-code Euler's method: $\frac{dy}{dx} = f(x, y)$ and $y(x_0) = y_0$.

- 1 Initialize variables, functions; set $h = \frac{x_1 - x_0}{N}$
- 2 Set $x = x_0$, $y = y_0$
- 3 While $x < x_{\text{end}}$ do
 $x_{i+1} = x_i + h$; $y_{i+1} = y_i + hf(x_i, y_i)$

Euler's method - example

First order reaction in a batch reactor:

$$\frac{dc}{dt} = -kc \quad \text{with} \quad c(t=0) = 1 \text{ mol m}^{-3}, \quad k = 1 \text{ s}^{-1}, \quad t_{\text{end}} = 2 \text{ s}$$

Time [s]	Concentration [mol m ⁻³]
$t_0 = 0$	$c_0 = 1.00$
$t_1 = t_0 + \Delta t$	$c_1 = c_0 + \Delta t \cdot (-kc_0)$
$= 0 + 0.1 = 0.1$	$= 1 + 0.1 \cdot (-1 \cdot 1) = 0.9$
$t_2 = t_1 + \Delta t$	$c_2 = c_1 + \Delta t \cdot (-kc_1)$
$= 0.1 + 0.1 = 0.2$	$= 0.9 + 0.1 \cdot (-1 \cdot 0.9) = 0.81$
$t_3 = t_2 + \Delta t$	$c_3 = c_2 + \Delta t \cdot (-kc_2)$
$= 0.2 + 0.1 = 0.3$	$= 0.81 + 0.1 \cdot (-1 \cdot 0.81) = 0.729$
...	...
$t_{i+1} = t_i + \Delta t$	$c_{i+1} = c_i + \Delta t \cdot (-kc_i)$
...	...
$t_{20} = 2.0$	$c_{20} = c_{19} + \Delta t \cdot (-kc_{19}) = 0.121577$

Euler's method - example

Problems with Euler's method

The question is: What step size, or how many steps to use?

- 1 *Accuracy* \Rightarrow need information on numerical error!
- 2 *Stability* \Rightarrow need information on stability limits!

Reaction rate: $k = 1 \text{ s}^{-1}$

Reaction rate: $k = 50 \text{ s}^{-1}$

Accuracy

Comparison with analytical solution for $k = 1 \text{ s}^{-1}$:

$$c(t) = c_0 \exp(-kt) \Rightarrow \zeta = 1 - \exp(-kt) \Rightarrow \zeta_{\text{analytical}} = 0.864665$$

N	ζ	$\frac{\zeta_{\text{numerical}} - \zeta_{\text{analytical}}}{\zeta_{\text{analytical}}}$
20	0.878423	0.015912
40	0.871488	0.007891
80	0.868062	0.003929
160	0.866360	0.001961
320	0.865511	0.000979

Accuracy

For Euler's method: Error halves when the number of grid points is doubled, i.e. error is proportional to Δt : first order method.

Error estimate:

$$\left. \frac{dx}{dt} \right|_{t_0} = \frac{x(t_0 + \Delta t) - x(t_0)}{\Delta t} + \frac{1}{2} \left. \frac{d^2x}{dt^2} \right|_{t_0} (\Delta t) + \mathcal{O}(\Delta t)^2$$

$$\frac{x(t_0 + \Delta t) - x(t_0)}{\Delta t} = f(x_0, t_0) - \frac{1}{2} \left. \frac{d^2x}{dt^2} \right|_{t_0} (\Delta t) + \mathcal{O}(\Delta t)^2$$

Errors and convergence rate

Convergence rate (or: order of convergence) r

$$\epsilon = \lim_{\Delta x \rightarrow 0} c(\Delta x)^r$$

- A first order method reduces the error by a factor 2 when increasing the number of steps by a factor 2
- A second order method reduces the error by a factor 4 when increasing the number of steps by a factor 2

What to do when there is no analytical solution available? Compare to calculations with different number of steps:

$\epsilon_1 = c(\Delta x_1)^r$ and $\epsilon_2 = c(\Delta x_2)^r$ and solve for r :

$$\frac{\epsilon_2}{\epsilon_1} = \frac{c(\Delta x_2)^r}{c(\Delta x_1)^r} = \left(\frac{\Delta x_2}{\Delta x_1} \right)^r \Rightarrow \log\left(\frac{\epsilon_2}{\epsilon_1}\right) = \log\left(\frac{\Delta x_2}{\Delta x_1}\right)^r$$

$$\Rightarrow r = \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{\Delta x_2}{\Delta x_1}\right)} = \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{N_1}{N_2}\right)} \quad \text{in the limit of } \Delta x \rightarrow 0 \quad \text{or} \quad N \rightarrow \infty$$

Today's outline

- Introduction
- Euler's method
 - Forward Euler
- Rates of convergence
- Runge-Kutta methods
 - RK2 methods
 - RK4 method
- Step size control
- Solving ODEs in Python

Errors and convergence rate

L_2 norm (Euclidean norm)

$$\|\mathbf{v}\|_2 = \sqrt{v_1^2 + v_2^2 + \dots + v_n^2} = \sqrt{\sum_{i=1}^n v_i^2}$$

L_∞ norm (maximum norm)

$$\|\mathbf{v}\|_\infty = \max(|v_1|, \dots, |v_n|)$$

Absolute difference

$$\epsilon_{\text{abs}} = \|\mathbf{y}_{\text{numerical}} - \mathbf{y}_{\text{analytical}}\|_{2,\infty}$$

Relative difference

$$\epsilon_{\text{rel}} = \left\| \frac{\mathbf{y}_{\text{numerical}} - \mathbf{y}_{\text{analytical}}}{\mathbf{y}_{\text{analytical}}} \right\|_{2,\infty}$$

Errors and convergence rate

Convergence rate (or: order of convergence) r

$$\epsilon = \lim_{\Delta x \rightarrow 0} c(\Delta x)^r$$

- A first order method reduces the error by a factor 2 when increasing the number of steps by a factor 2
- A second order method reduces the error by a factor 4 when increasing the number of steps by a factor 2

Computing the rate of convergence

When the analytical solution is available, choose ❶ or ❷ for a particular number of grid points N :

❶ Compute the relative or absolute error vector $\bar{\epsilon}$. Take the norm to compute a single error value ϵ following:

- Based on L_1 -norm: $\epsilon = \frac{\|\bar{\epsilon}\|_1}{N}$
- Based on L_2 -norm: $\epsilon = \frac{\|\bar{\epsilon}\|_2}{\sqrt{N}}$
- Based on L_∞ -norm: $\epsilon = \|\bar{\epsilon}\|_\infty$

❷ Compute the relative or absolute error at a single indicative points (e.g. middle of domain, outlet).

Compare to calculations with different number of steps: $\epsilon_1 = c(\Delta x_1)^r$ and $\epsilon_2 = c(\Delta x_2)^r$ and solve for r :

$$\frac{\epsilon_2}{\epsilon_1} = \frac{c(\Delta x_2)^r}{c(\Delta x_1)^r} = \left(\frac{\Delta x_2}{\Delta x_1} \right)^r \Rightarrow \log\left(\frac{\epsilon_2}{\epsilon_1}\right) = \log\left(\frac{\Delta x_2}{\Delta x_1}\right)^r$$

$$\Rightarrow r = \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{\Delta x_2}{\Delta x_1}\right)} = \frac{\log\left(\frac{\epsilon_2}{\epsilon_1}\right)}{\log\left(\frac{N_1}{N_2}\right)} \quad \text{in the limit of } \Delta x \rightarrow 0 \text{ or } N \rightarrow \infty$$

Computing the rate of convergence

When the analytical solution is **not** available:

- 1 Compute the solution with $N + 1$, N , $N - 1$ and $N - 2$ grid points
- 2 Select a single indicative grid point (e.g. middle of domain, outlet) that lies at exactly the same position in each computation
- 3 Use the solution c at this grid point for various grid sizes to compute:

$$r = \frac{\log \frac{c_{N+1} - c_N}{c_N - c_{N-1}}}{\log \frac{c_N - c_{N-1}}{c_{N-1} - c_{N-2}}}$$

- 4 Alternative for simulations with $2N$, N and $\frac{N}{2}$ grid points:

$$r = \frac{\log \left| \frac{c_{2N} - c_N}{c_N - c_{\frac{N}{2}}} \right|}{\log \left| \frac{N}{2N} \right|}$$

Example: Euler's method — order of convergence

N	ζ	$\frac{\zeta_{\text{numerical}} - \zeta_{\text{analytical}}}{\zeta_{\text{analytical}}}$	$r = \frac{\log\left(\frac{\epsilon_j}{\epsilon_{j-1}}\right)}{\log\left(\frac{N_{j-1}}{N_j}\right)}$
20	0.878423	0.015912	—
40	0.871488	0.007891	1.011832
80	0.868062	0.003929	1.005969
160	0.866360	0.001961	1.002996
320	0.865511	0.000979	1.001500

⇒ Euler's method is a first order method (as we already knew from the truncation error analysis)

Wouldn't it be great to have a method that can give the answer using much less steps? ⇒
Higher order methods

Today's outline

- Introduction
- Euler's method
 - Forward Euler
- Rates of convergence
- Runge-Kutta methods
 - RK2 methods
 - RK4 method
- Step size control
- Solving ODEs in Python

Runge-Kutta methods

Propagate a solution by combining the information of several Euler-style steps (each involving one function evaluation) to match a Taylor series expansion up to some higher order.

Euler: $y_{i+1} = y_i + hf(x_i, y_i)$ with $h = \Delta x$, i.e. slope = $k_1 = f(x_i, y_i)$.

Euler's method

RK2 method

Classical second order Runge-Kutta (RK2) method

This method is also called Heun's method, or improved Euler method:

- 1 Approximate the slope at x_i : $k_1 = f(x_i, y_i)$
- 2 Approximate the slope at x_{i+1} : $k_2 = f(x_{i+1}, y_{i+1})$ where we use Euler's method to approximate $y_{i+1} = y_i + hf(x_i, y_i) = y_i + hk_1$
- 3 Perform an Euler step with the average of the slopes: $y_{i+1} = y_i + h \frac{1}{2}(k_1 + k_2)$

In pseudocode:

```
x = x0, y = y0
while x < xend do
  xi+1 = xi + h
  k1 = f(xi, yi)
  k2 = f(xi + h, yi + hk1)
  yi+1 = yi + h  $\frac{1}{2}$  (k1 + k2)
end while
```

Runge-Kutta methods — derivation

$$\frac{dy}{dx} = f(x, y(x))$$

Using Taylor series expansion: $y_{i+1} = y_i + h \left. \frac{dy}{dx} \right|_i + \frac{h^2}{2} \left. \frac{d^2y}{dx^2} \right|_i + \mathcal{O}(h^3)$

$$\left. \frac{dy}{dx} \right|_i = f(x_i, y_i) \equiv f_i$$

$$\left. \frac{d^2y}{dx^2} \right|_i = \left. \frac{d}{dx} f(x, y(x)) \right|_i = \left. \frac{\partial f}{\partial x} \right|_i + \left. \frac{\partial f}{\partial y} \right|_i \left. \frac{dy}{dx} \right|_i = \left. \frac{\partial f}{\partial x} \right|_i + \left. \frac{\partial f}{\partial y} \right|_i f_i \quad (\text{chain rule})$$

Substitution gives:

$$y_{i+1} = y_i + hf_i + \frac{h^2}{2} \left(\left. \frac{\partial f}{\partial x} \right|_i + \left. \frac{\partial f}{\partial y} \right|_i f_i \right) + \mathcal{O}(h^3)$$

$$y_{i+1} = y_i + \frac{h}{2} f_i + \frac{h}{2} \left(f_i + h \left. \frac{\partial f}{\partial x} \right|_i + hf_i \left. \frac{\partial f}{\partial y} \right|_i \right) + \mathcal{O}(h^3)$$

Runge-Kutta methods — derivation

Note multivariate Taylor expansion:

$$\begin{aligned} f(x_i + h, y_i + k) &= f_i + h \left. \frac{\partial f}{\partial x} \right|_i + k \left. \frac{\partial f}{\partial y} \right|_i + \mathcal{O}(h^2) \\ &\Rightarrow \frac{h}{2} \left(f_i + h \left. \frac{\partial f}{\partial x} \right|_i + hf_i \left. \frac{\partial f}{\partial y} \right|_i \right) = \frac{h}{2} f(x_i + h, y_i + hf_i) + \mathcal{O}(h^3) \end{aligned}$$

Concluding:

$$y_{i+1} = y_i + \frac{h}{2} f_i + \frac{h}{2} f(x_i + h, y_i + hf_i) + \mathcal{O}(h^3)$$

Rewriting:

$$\begin{aligned} k_1 &= f(x_i, y_i) \\ k_2 &= f(x_i + h, y_i + hk_1) \\ \Rightarrow y_{i+1} &= y_i + \frac{h}{2} (k_1 + k_2) \end{aligned}$$

Runge-Kutta methods — derivation

Generalization: $y_{i+1} = y_i + h(b_1k_1 + b_2k_2) + \mathcal{O}(h^3)$

with $k_1 = f_i$, $k_2 = f(x_i + c_2h, y_i + a_{2,1}hk_1)$

(Note that classical RK2: $b_1 = b_2 = \frac{1}{2}$ and $c_2 = a_{2,1} = 1$.)

Bivariate Taylor expansion:

$$f(x_i + c_2h, y_i + a_{2,1}hk_1) = f_i + c_2h \left. \frac{\partial f}{\partial x} \right|_i + a_{2,1}hk_1 \left. \frac{\partial f}{\partial y} \right|_i + \mathcal{O}(h^2)$$

$$y_{i+1} = y_i + h(b_1k_1 + b_2k_2) + \mathcal{O}(h^3)$$

$$= y_i + h \left[b_1f_i + b_2f(x_i + c_2h, y_i + a_{2,1}hk_1) \right] + \mathcal{O}(h^3)$$

$$= y_i + h \left[b_1f_i + b_2 \left\{ f_i + c_2h \left. \frac{\partial f}{\partial x} \right|_i + a_{2,1}hk_1 \left. \frac{\partial f}{\partial y} \right|_i + \mathcal{O}(h^2) \right\} \right] + \mathcal{O}(h^3)$$

$$= y_i + h(b_1 + b_2)f_i + h^2b_2 \left(c_2 \left. \frac{\partial f}{\partial x} \right|_i + a_{2,1}f_i \left. \frac{\partial f}{\partial y} \right|_i \right) + \mathcal{O}(h^3)$$

Comparison with Taylor:

$$y_{i+1} = y_i + hf_i + \frac{h^2}{2} \left(\left. \frac{\partial f}{\partial x} \right|_i + \left. \frac{\partial f}{\partial y} \right|_i f_i \right) + \mathcal{O}(h^3)$$

Using $b_1 + b_2 = 1$, $c_2b_2 = \frac{1}{2}$, $a_{2,1}b_2 = \frac{1}{2} \Rightarrow 3$ eqns and 4 unknowns \Rightarrow multiple possibilities!

Runge-Kutta methods — derivation

$$y_{i+1} = y_i + h(b_1 + b_2)f_i + h^2 b_2 \left(c_2 \left. \frac{\partial f}{\partial x} \right|_i + a_{2,1} f_i \left. \frac{\partial f}{\partial y} \right|_i \right) + \mathcal{O}(h^3)$$

$$y_{i+1} = y_i + hf_i + \frac{h^2}{2} \left(\left. \frac{\partial f}{\partial x} \right|_i + \left. \frac{\partial f}{\partial y} \right|_i f_i \right) + \mathcal{O}(h^3)$$

⇒ 3 eqns and 4 unknowns ⇒ multiple possibilities!

❶ Classical RK2:

$$b_1 = b_2 = \frac{1}{2} \text{ and } c_2 = a_{2,1} = 1$$

❷ Midpoint rule (modified Euler):

$$b_1 = 0, b_2 = 1, c_2 = a_{2,1} = \frac{1}{2}$$

Second order Runge-Kutta methods

Classical RK2 method
(= Heun's method, improved Euler method)

$$\begin{aligned} k_1 &= f_i \\ k_2 &= f(x_i + h, y_i + hk_1) \\ y_{i+1} &= y_i + \frac{1}{2}h(k_1 + k_2) \end{aligned}$$

Explicit midpoint rule (modified Euler method)

$$\begin{aligned} k_1 &= f_i \\ k_2 &= f(x_i + \frac{1}{2}h, y_i + \frac{1}{2}hk_1) \\ y_{i+1} &= y_i + hk_2 \end{aligned}$$

Second order Runge-Kutta method — Example

First order reaction in a batch reactor: $\frac{dc}{dt} = -kc$ with $c(t=0) = 1 \text{ mol m}^{-3}$, $k = 1 \text{ s}^{-1}$, $t_{\text{end}} = 2 \text{ s}$.

Time [s]	C [mol m ⁻³]	$k_1 = hf(x_i, y_i)$	$k_2 = hf(x_i + \frac{1}{2}h, y_i + \frac{1}{2}k_1)$

⇒ RK4 is a fourth order method: Doubling the number of cells reduces the error by a factor 16!

Can we do even better?

Today's outline

- Introduction
- Euler's method
 - Forward Euler
- Rates of convergence
- Runge-Kutta methods
 - RK2 methods
 - RK4 method
- Step size control
- Solving ODEs in Python

Adaptive step size control

The step size (be it either position, time or both (PDEs)) cannot be decreased indefinitely to favour a higher accuracy, since each additional grid point causes additional computation time. It may be wise to adapt the step size according to the computation requirements.

Globally two different approaches can be used:

- ① Step doubling: compare solutions when taking one full step or two consecutive half steps
- ② Embedded methods: Compare solutions when using two approximations of different order

Adaptive step size control: step doubling

- RK4 with one large step of h : $y_{i+1} = y_1 + ch^5 + \mathcal{O}(h^6)$
- RK4 with two steps of $\frac{1}{2}h$: $y_{i+1} = y_2 + 2c(\frac{1}{2}h)^5 + \mathcal{O}(h^6)$

Adaptive step size control: step doubling

- Estimation of truncation error by comparing y_1 and y_2 :

$$\Delta = y_2 - y_1$$

- If Δ too large, reduce step size for accuracy
- If Δ too small, increase step size for efficiency.
- Ignoring higher order terms and solving for c :
$$\Delta = \frac{15}{16}ch^5 \Rightarrow ch^5 = \frac{16}{15}\Delta \Rightarrow y_{i+1} = y_2 + \frac{\Delta}{15} + \mathcal{O}(h^6)$$

(local Richardson extrapolation)

Note that when we specify a tolerance tol , we can estimate the maximum allowable step size as: $h_{\text{new}} = \alpha h_{\text{old}} \left| \frac{tol}{\Delta} \right|^{\frac{1}{5}}$ with α a safety factor (typically $\alpha = 0.9$).

Adaptive step size control: embedded methods

Use a special fourth and a fifth order Runge Kutta method to approximate y_{i+1}

- The fourth order method is special because we want to use the same positions for the evaluation for computational efficiency.
- RK45 is the preferred method (minimum number of function evaluations) (this is the default method in `scipy.integrate.solve_ivp`).

Solving ODEs in Python

SciPy provides convenient procedures to solve (systems of) ODEs automatically.

The procedure is as follows:

- 1 Create a function that specifies the ODE(s). Specifically, this function returns the $\frac{dy}{dx}$ value (vector).
- 2 Initialise solver variables and settings (e.g. step size, initial conditions, tolerance)
- 3 Call the ODE solver function, passing the ODE function as argument
 - The ODE solver will return a solution object (e.g. `sol`), with attribute `sol.t` as the independent variable vector, and a `sol.y` the solution vector (or matrix for systems of ODEs).

Solving ODEs in Python: example 1

We solve the system: $\frac{dx}{dt} = -k_1x + k_2, k_1 = 0.2, k_2 = 2.5$

- Create a lambda function:

```
1 dydx = lambda x,y: (-0.2*y + 2.5)
```

- Solve with a call to `solve_ivp(function, timespan, initial_condition)`:

```
1 from scipy.integrate import solve_ivp  
2 sol = solve_ivp(dydx, tspan, y0)
```

- Draw the results by calling the relevant Matplotlib commands:

```
3 import matplotlib.pyplot as plt  
4 plt.plot(sol.t, sol.y[0,:])  
5 plt.show()
```

Solving ODEs in Python: example 2

We solve the system: $\frac{dx}{dt} = \begin{cases} -\frac{k_1}{x^2} & t \leq 10 \\ \frac{k_2}{x} - \frac{k_1}{x^2} & t > 10 \end{cases}$ with $k_1 = 0.5, k_2 = 1, x(0) = 2$

Create an ODE function

```
1 def myEqnFunction(t,x):  
2     k1 = 0.5;  
3     k2 = 1;  
4     dxdt = int(t>10)*k2/x - k1/x**2;  
5     return dxdt
```

Create a solution script

```
1 tspan = [0, 20]  
2 x_init = [2]  
3 sol = solve_ivp(myEqnFunction, tspan, x_init, rtol=1e-8, atol=1e-6)
```

Solving ODEs in Python: example 2

Plot the solution:

```
1 plt.plot(sol.t, sol.y[0,:], 'r-x')  
2 plt.grid()  
3 plt.show()
```

Note the refinement in regions where large changes occur.

Solving ODEs in Python: example

A few notes on working with `scipy.integrate.solve_ivp` and other ODE solvers. If we want to give additional arguments (e.g. k_1 and k_2) to our ODE function, we can list them in the function line:

```
1 func = lambda t,x,k1,k2: k1*x+k2
2 # or
3 def func(t,x,k1,k2):
4     return k1*x+k2
```

The additional arguments can now be set in the solver script by *adding them as args list*:

```
1 sol = solve_ivp(func,[0,5],[1],args=(k1, k2))
```

Of course, in the solver script, the variables do not have to be called k_1 and k_2 :

```
1 sol = solve_ivp(func,[0,5],[1],args=(q, u))
```

These variables may be of any type (scalar, vector, dictionary, list). For carrying over many variables, a dictionary is useful and descriptive.

Solving systems of ODEs in Python: example

You have noticed that the step size in t varies. This is because we have given just the begin and end times of our time span:

```
1 tspan = [0, 5];
```

You can also obtain the solution at specific points, by supplying a list t_eval :

```
1 sol = solve_ivp(func,tspan,[1],args=(some_k1, some_k2),t_eval=np.linspace(tspan[0],tspan[1],31))
```

This example provides 31 explicit time steps between 0 and 5 seconds. Note that the results are interpolated to these data points afterwards; you do not influence the efficiency and accuracy of the solver algorithm this way!

Problems with Euler's method: instability

Consider the ODE:

$$\frac{dy}{dx} = f(x, y(x)) \quad \text{with} \quad y(x=0) = y_0$$

First order approximation of derivative: $\frac{dy}{dx} = \frac{y_{i+1} - y_i}{\Delta x}$.

Where to evaluate the function f ?

- ① Evaluation at x_i : Explicit Euler method (forward Euler)
- ② Evaluation at x_{i+1} : Implicit Euler method (backward Euler)

Problems with Euler's method: instability – forward Euler

Explicit Euler method (forward Euler):

- Use values at x_i :

$$\frac{y_{i+1}-y_i}{\Delta x} = f(x_i, y_i) \Rightarrow y_{i+1} = y_i + hf(x_i, y_i).$$

- This is an explicit equation for y_{i+1} in terms of y_i .
- It can give instabilities with large function values.

Consider the first order batch reactor:

$$\frac{dc}{dt} = -kc \Rightarrow c_{i+1} = c_i - k c_i \Delta t \Rightarrow \frac{c_{i+1}}{c_i} = 1 - k\Delta t$$

It follows that unphysical results are obtained for $k\Delta t \geq 1$!!

Stability requirement

$$k\Delta t < 1$$

(but probably accuracy requirements are more stringent here!)

Problems with Euler's method: instability – backward Euler

Implicit Euler method (backward Euler):

- Use values at x_{i+1} : $\frac{y_{i+1}-y_i}{\Delta x} = f(x_{i+1}, y_{i+1}) \Rightarrow y_{i+1} = y_i + hf(x_{i+1}, y_{i+1})$.
- This is an implicit equation for y_{i+1} , because it also depends on terms of y_{i+1} .

Consider the first order batch reactor:

$$\frac{dc}{dt} = -kc \Rightarrow c_{i+1} = c_i - k c_{i+1} \Delta t \Rightarrow \frac{c_{i+1}}{c_i} = \frac{1}{1 + k\Delta t}$$

This equation does never give unphysical results!

The implicit Euler method is *unconditionally stable*
(but maybe not very accurate or efficient).

Semi-implicit Euler method

Usually f is a non-linear function of y , so that linearization is required (recall Newton's method).

$$\frac{dy}{dx} = f(y) \Rightarrow y_{i+1} = y_i + hf(y_{i+1}) \quad \text{using} \quad f(y_{i+1}) = f(y_i) + \left. \frac{df}{dy} \right|_i (y_{i+1} - y_i) + \dots$$

$$\Rightarrow y_{i+1} = y_i + h \left[f(y_i) + \left. \frac{df}{dy} \right|_i (y_{i+1} - y_i) \right]$$

$$\Rightarrow \left(1 - h \left. \frac{df}{dy} \right|_i \right) y_{i+1} = \left(1 - h \left. \frac{df}{dy} \right|_i \right) y_i + hf(y_i)$$

$$\Rightarrow y_{i+1} = y_i + h \left(1 - h \left. \frac{df}{dy} \right|_i \right)^{-1} f(y_i)$$

For the case that $f(x, y(x))$ we could add the variable x as an additional variable $y_{n+1} = x$. Or add one fully implicit Euler step (which avoids the computation of $\frac{\partial f}{\partial x}$):

$$y_{i+1} = y_i + hf(x_{i+1}, y_{i+1}) \Rightarrow y_{i+1} = y_i + h \left(1 - h \left. \frac{df}{dy} \right|_i \right)^{-1} f(x_{i+1}, y_i)$$

Implicit Euler's method - implementation

A basic function of the implicit Euler method is given in `ode_scalar_implicit.py`:

```

1 def implicit_euler(func, c0, t0, tend, n):
2     h = 1e-8
3     dt = (tend - t0)/n
4     times = np.linspace(t0,tend,n+1)
5     c = np.zeros(n+1)
6     c[0] = c0
7     for i,t in enumerate(times[:-1]):
8         f = func(c[i],t)
9         fh = func(c[i]+h,t)
10        dfdc = (fh - f)/h
11        c[i+1] = c[i] + dt*f/(1 - dt*dfdc)
12        print(f"{t:=0.4f}, c: {c[i+1]:.8f}")
13    print(f"t={times[-1]:0.4f}, c: {c[-1]:.8f}")
14    return times, c

```

```

1 from ode_scalar_implicit import implicit_euler
2 t,c = implicit_euler(lambda c,t: -1.0*c**2, 1, 0, 2,
3                       10)
4 plt.plot(t,c,'-o',label='Implicit Euler')
5 print(f"Conversion = {conv_e}")

```

```

t=0.0000, c: 0.85714286
t=0.2000, c: 0.74772036
t=0.4000, c: 0.66164680

```

Semi-implicit Euler method - example

Second order reaction in a batch reactor:

$$\frac{dc}{dt} = -kc^2 \text{ with } c_0 = 1 \text{ mol m}^{-3}, k = 1 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}, t_{\text{end}} = 2 \text{ s}$$

Analytical solution: $c(t) = \frac{c_0}{1+kc_0t}$

Define $f = -kc^2$, then $\frac{df}{dc} = -2kc \Rightarrow c_{i+1} = c_i - \frac{hkc_i^2}{1+2hkc_i}$.

N	ζ	$\frac{\zeta_{\text{numerical}} - \zeta_{\text{analytical}}}{\zeta_{\text{analytical}}}$	$r = \frac{\log\left(\frac{\epsilon_i}{\epsilon_{i-1}}\right)}{\log\left(\frac{N_{j-1}}{N_j}\right)}$
20	0.654066262	1.89×10^{-2}	—
40	0.660462687	9.31×10^{-3}	1.02220
80	0.663589561	4.62×10^{-3}	1.01162
160	0.665134433	2.30×10^{-3}	1.00594
320	0.665902142	1.15×10^{-3}	1.00300

Second order implicit method: Implicit midpoint method

Implicit midpoint rule (second order)	Explicit midpoint rule (modified Euler method)
$y_{i+1} = y_i + hf\left(x_i + \frac{1}{2}h, \frac{1}{2}(y_i + y_{i+1})\right)$	$y_{i+1} = y_i + hf\left(x_i + \frac{1}{2}h, y_i + \frac{1}{2}hk_1\right)$

in case $f(y)$ then:

$$f\left(\frac{1}{2}(y_i + y_{i+1})\right) = f_i + \left.\frac{df}{dy}\right|_i \left(\frac{1}{2}(y_i + y_{i+1}) - y_i\right) = f_i + \frac{1}{2} \left.\frac{df}{dy}\right|_i (y_{i+1} - y_i)$$

Implicit midpoint rule reduces to:

$$\begin{aligned} y_{i+1} &= y_i + hf_i + \frac{h}{2} \left.\frac{df}{dy}\right|_i (y_{i+1} - y_i) \\ \Rightarrow \left(1 - \frac{h}{2} \left.\frac{df}{dy}\right|_i\right) y_{i+1} &= \left(1 - \frac{h}{2} \left.\frac{df}{dy}\right|_i\right) y_i + hf_i \end{aligned}$$

$$\Rightarrow y_{i+1} = y_i + h \left(1 - \frac{h}{2} \left.\frac{df}{dy}\right|_i\right)^{-1} f_i$$

Implicit midpoint method — example

Second order reaction in a batch reactor:

$$\frac{dc}{dt} = -kc^2 \text{ with } c_0 = 1 \text{ mol m}^{-3}, k = 1 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}, t_{\text{end}} = 2 \text{ s (Analytical solution: } c(t) = \frac{c_0}{1+kc_0 t}).$$

Define $f = -kc^2$, then $\frac{df}{dc} = -2kc$.

Substitution:

$$\begin{aligned} c_{i+1} &= c_i + h \left(1 - \frac{h}{2} \cdot (-2kc_i) \right)^{-1} \cdot (-kc_i^2) \\ &= c_i - \frac{hkc_i^2}{1+hkc_i} = \frac{c_i + hkc_i^2 - hkc_i^2}{1+hkc_i} \Rightarrow c_{i+1} = \frac{c_i}{1+hkc_i} \end{aligned}$$

You will find that this method is exact for all step sizes h because of the quadratic source term!

Implicit midpoint method — example

Second order reaction in a batch reactor:

$$\frac{dc}{dt} = -kc^2 \text{ with } c_0 = 1 \text{ mol m}^{-3}, k = 1 \text{ m}^3 \text{ mol}^{-1} \text{ s}^{-1}, t_{\text{end}} = 2 \text{ s}$$

$$\text{Analytical solution: } c(t) = \frac{c_0}{1+kc_0t}$$

$$c_{i+1} = \frac{c_i}{1+hkc_i}$$

N	ζ	$\frac{\zeta_{\text{numerical}} - \zeta_{\text{analytical}}}{\zeta_{\text{analytical}}}$	$r = \frac{\log\left(\frac{\epsilon_i}{\epsilon_{i-1}}\right)}{\log\left(\frac{N_{i-1}}{N_i}\right)}$

Today's outline

● Introduction

- Backward Euler
- Implicit midpoint method

● Systems of ODEs

- Solution methods for systems of ODEs
- Solving systems of ODEs in Python
- Stiff systems of ODEs

● Boundary value problems

- Shooting method

● Conclusion

Systems of ODEs

A system of ODEs is specified using vector notation:

$$\frac{d\mathbf{y}}{dx} = \mathbf{f}(x, \mathbf{y}(x))$$

for

$$\frac{dy_1}{dx} = f_1(x, y_1(x), y_2(x)) \quad \text{or} \quad f_1(x, y_1, y_2)$$

$$\frac{dy_2}{dx} = f_2(x, y_1(x), y_2(x)) \quad \text{or} \quad f_2(x, y_1, y_2)$$

The solution techniques discussed before can also be used to solve systems of equations.

Systems of ODEs: Explicit methods

Forward Euler method

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h\mathbf{f}(x_i, \mathbf{y}_i)$$

Improved Euler method (classical RK2)

$$\mathbf{y}_{i+1} = \mathbf{y}_i + \frac{h}{2}(\mathbf{k}_1 + \mathbf{k}_2) \quad \text{using} \quad \begin{aligned} \mathbf{k}_1 &= \mathbf{f}(x_i, \mathbf{y}_i) \\ \mathbf{k}_2 &= \mathbf{f}(x_i + h, \mathbf{y}_i + h\mathbf{k}_1) \end{aligned}$$

Modified Euler method (midpoint rule)

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h\mathbf{k}_2 \quad \text{using} \quad \begin{aligned} \mathbf{k}_1 &= \mathbf{f}(x_i, \mathbf{y}_i) \\ \mathbf{k}_2 &= \mathbf{f}\left(x_i + \frac{h}{2}, \mathbf{y}_i + \frac{h}{2}\mathbf{k}_1\right) \end{aligned}$$

Systems of ODEs: Explicit methods

Classical fourth order Runge-Kutta method (RK4)

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h \left(\frac{\mathbf{k}_1}{6} + \frac{1}{3} (\mathbf{k}_2 + \mathbf{k}_3) + \frac{\mathbf{k}_4}{6} \right)$$

$$\mathbf{k}_1 = \mathbf{f}(x_i, \mathbf{y}_i)$$

$$\mathbf{k}_2 = \mathbf{f}\left(x_i + \frac{h}{2}, \mathbf{y}_i + \frac{h}{2}\mathbf{k}_1\right)$$

using

$$\mathbf{k}_3 = \mathbf{f}\left(x_i + \frac{h}{2}, \mathbf{y}_i + \frac{h}{2}\mathbf{k}_2\right)$$

$$\mathbf{k}_4 = \mathbf{f}(x_i + h, \mathbf{y}_i + h\mathbf{k}_3)$$

Solving systems of ODEs in Python

Solving systems of ODEs in Python is completely analogous to solving a single ODE:

- ❶ Create a function that specifies the ODEs. This function returns the $\frac{dy}{dx}$ vector.
- ❷ Initialise solver variables and settings (e.g. step size, initial conditions, tolerance), in a separate script. Initial conditions and tolerances should be given per-equation, i.e. as a vector.
- ❸ Call the ODE solver function, using a function argument to the ODE function described in point 1.
 - The ODE solver will return the vector for the independent variable (e.g. time), and a solution matrix, with a column as the solution for each equation in the system.

Solving systems of ODEs in Python: example

We solve the system $\frac{dx_0}{dt} = ax_0 - x_1$, $\frac{dx_1}{dt} = bx_1 + x_0$, with $a = -1$ and $b = -2$:

- Create an ODE function:

```

1 # Example scipy solve_ivp/Example scipy solve_ivp vector.py
2 def func(t, x, a, b):
3     #output can be of list or np.array type:
4     dxdt = np.zeros(2)
5
6     dxdt[0] = a*x[0] - x[1]
7     dxdt[1] = b*x[1] + x[0]
8     return dxdt

```

- Solve by calling solve_ivp

```

1 from scipy.integrate import solve_ivp
2 x_init = [0,1]; % Initial conditions
3 tspan = [0,10]; % Time span
4 sol = solve_ivp(func, tspan, x_init, args=(-1,-2), rtol=1e-12)

```

Solving systems of ODEs in Python: example

Plot the solution (note: the solution is attribute `sol.y`):

```
1 import matplotlib.pyplot as plt
2 plt.plot(sol.t, sol.y[0], 'r-x', linewidth=2)
3 plt.plot(sol.t, sol.y[1], 'b-o', linewidth=2)
```

Solving ODEs in Python: example

A few notes on working with `scipy.integrate.solve_ivp` and other ODE solvers. If we want to give additional arguments (e.g. k_1 and k_2) to our ODE function, we can list them in the function line:

```
1 func = lambda t,x,k1,k2: k1*x+k2
2 # or
3 def func(t,x,k1,k2):
4     return k1*x+k2
```

The additional arguments can now be set in the solver script by *adding them as args list*:

```
1 sol = solve_ivp(func,[0,5],[1],args=(k1, k2))
```

Of course, in the solver script, the variables do not have to be called k_1 and k_2 :

```
1 sol = solve_ivp(func,[0,5],[1],args=(q, u))
```

These variables may be of any type (scalar, vector, dictionary, list). For carrying over many variables, a dictionary is useful and descriptive.

Solving systems of ODEs in Python: example

You may have noticed that the step size in t varies. This happens when only the begin and end times of the time span are defined, and `scipy.integrate.solve_ivp` uses adaptive step size for efficiency:

```
1 tspan = [0, 10]
```

You can also retrieve the solution at specific steps, by supplying all steps explicitly as an additional argument to `solve_ivp`, e.g.:

```
1 sol = solve_ivp(func, tspan, x_init, args=(-1,-2), t_eval=np.linspace(0, 10, 101), rtol=1e-12)
```

This example provides 101 explicit time steps between 0 and 10 seconds. It can be useful if you need a direct comparison with e.g. measurements at specific times.

Note that this is an interpolated result. The solver uses, in the background, still the adaptive step size functionality!

Systems of ODEs: Implicit methods

Backward Euler method

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h \left(\mathbf{I} - h \left. \frac{d\mathbf{f}}{d\mathbf{y}} \right|_i \right)^{-1} \mathbf{f}(\mathbf{y}_i)$$

Implicit midpoint method

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h \left(\mathbf{I} - \frac{h}{2} \left. \frac{d\mathbf{f}}{d\mathbf{y}} \right|_i \right)^{-1} \mathbf{f}(\mathbf{y}_i)$$

Stiff systems of ODEs

A system of ODEs can be stiff and require a different solution method. For example:

$$\frac{dc_1}{dt} = 998c_1 + 1998c_2 \quad \frac{dc_2}{dt} = -999c_1 - 1999c_2$$

with boundary conditions $c_1(t=0) = 1$ and $c_2(t=0) = 0$.

The analytical solution is:

$$c_1 = 2e^{-t} - e^{-1000t} \quad c_2 = -e^{-t} + e^{-1000t}$$

For the explicit method we require $\Delta t < 10^{-3}$ despite the fact that the term is completely negligible, but essential to keep stability.

The “disease” of stiff equations: we need to follow the solution on the shortest length scale to maintain stability of the integration, although accuracy requirements would allow a much larger time step.

Demonstration with example

Forward Euler (explicit)

$$\frac{c_{1,i+1} - c_{1,i}}{dt} = 998c_{1,i} + 1998c_{2,i}$$

$$\frac{c_{2,i+1} - c_{2,i}}{dt} = -999c_{1,i} - 1999c_{2,i}$$

$$\Rightarrow \begin{aligned} c_{1,i+1} &= (1 + 998\Delta t)c_{1,i} + 1998\Delta tc_{2,i} \\ c_{2,i+1} &= -999\Delta tc_{1,i} + (1 - 1999\Delta t)c_{2,i} \end{aligned}$$

Demonstration with example

Backward Euler (implicit)

$$\frac{c_{1,i+1} - c_{1,i}}{\Delta t} = 998c_{1,i+1} + 1998c_{2,i+1}$$

$$\frac{c_{2,i+1} - c_{2,i}}{\Delta t} = -999c_{1,i+1} - 1999c_{2,i+1}$$

$$\Rightarrow (1 - 998\Delta t)c_{1,i+1} - 1998\Delta tc_{2,i+1} = c_{1,i}$$

$$999\Delta tc_{1,i+1} + (1 + 1999\Delta t)c_{2,i+1} = c_{2,i}$$

$$A\mathbf{c}_{i+1} = \mathbf{c}_i \text{ with } A = \begin{pmatrix} 1 - 998\Delta t & -1998\Delta t \\ 999\Delta t & 1 + 1999\Delta t \end{pmatrix} \text{ and } \mathbf{b} = \begin{pmatrix} c_{1,i} \\ c_{2,i} \end{pmatrix}$$

Demonstration with example

Backward Euler (implicit) $A\mathbf{c}_{i+1} = \mathbf{c}_i$ with $A = \begin{pmatrix} 1 - 998\Delta t & -1998\Delta t \\ 999\Delta t & 1 + 1999\Delta t \end{pmatrix}$ and $\mathbf{b} = \begin{pmatrix} c_{1,i} \\ c_{2,i} \end{pmatrix}$

Cramers rule:

$$c_{1,i+1} = \frac{\begin{vmatrix} c_{1,i} & -1998\Delta t \\ c_{2,i} & 1 + 1999\Delta t \end{vmatrix}}{\det A} = \frac{(1+1999\Delta t)c_{1,i} + 1998\Delta t c_{2,i}}{(1-998\Delta t)(1+1999\Delta t) + 1998 \cdot 999\Delta t^2}$$

$$c_{2,i+1} = \frac{\begin{vmatrix} 1 - 998\Delta t & c_{1,i} \\ 999\Delta t & c_{2,i} \end{vmatrix}}{\det A} = \frac{-999\Delta t c_{1,i} + (1-998\Delta t)c_{2,i}}{(1-998\Delta t)(1+1999\Delta t) + 1998 \cdot 999\Delta t^2}$$

Forward Euler: $\Delta t \leq 0.001$ for stability

Backward Euler: always stable, even for $\Delta t > 100$ (but then not very accurate!)

Demonstration with example

Cure for stiff problems: use implicit methods! To find out whether your system is stiff: check whether one of the eigenvalues have an imaginary part

Implicit methods in Python

SciPy offers a solver that detects stiff systems, using `method='LSODA'`.

$$\frac{dc_1}{dt} = 998c_1 + 1998c_2 \quad \frac{dc_2}{dt} = -999c_1 - 1999c_2, \quad c_1(0) = 1, \quad c_2(0) = 0$$

- Create the ode function (see `slide_example_solve_ivp_implicit.py`)

```
1 function [dcdt] = stiff_ode(t,c)
2 dcdt = zeros(2,1); % Pre-allocation
3 dcdt(1) = 998 * c(1) + 1998*c(2);
4 dcdt(2) = -999 * c(1) - 1999*c(2);
5 return
```

- Compare the resolution of the solutions (see next slide)

```
1 sol1 = solve_ivp(stiff_ode, [0, 1], [1, 0])
2 # plot sol1
3 sol2 = solve_ivp(stiff_ode, [0, 1], [1, 0], method = 'LSODA')
4 # plot sol2
```

Implicit methods in Python

Default settings

Method: LSODA

The explicit solver requires 1245 data points (default settings), the implicit solver just 48!

Implicit methods in Python: Generic backward Euler

How to make a generic Backward Euler implementation? Recall the update formula:

$$\mathbf{y}_{i+1} = \mathbf{y}_i + h \left(\mathbf{I} - h \left. \frac{d\mathbf{f}}{d\mathbf{y}} \right|_i \right)^{-1} \mathbf{f}(\mathbf{y}_i)$$

- Set up input: Number of steps, end time, initial conditions
- Preallocate and calculate: create a full time vector, calculate the step size h , preallocate y with zeros and store the initial condition as the first y .
- Loop over the number of iterations:
 - Compute the Jacobian: calculate the function both for y_i as well as for $y_i + s$, where s is a very small number. Recall:

$$\frac{df}{dy} = \frac{f(y+s) - f(y)}{s}$$

- Compute the update formula for y_{i+1} . Use `eye`, `inv`.

Today's outline

● Introduction

- Backward Euler
- Implicit midpoint method

● Systems of ODEs

- Solution methods for systems of ODEs
- Solving systems of ODEs in Python
- Stiff systems of ODEs

● Boundary value problems

- Shooting method

● Conclusion

Importance of boundary conditions

The nature of boundary conditions determines the appropriate numerical method. Classification into 2 main categories:

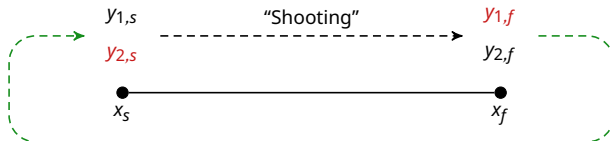

- *Initial value problems (IVP)*

We know the values of all y_i at some starting position x_s , and it is desired to find the values of y_i at some final point x_f .

- *Boundary value problems (BVP)*

Boundary conditions are specified at more than one x . Typically, some of the BC are specified at x_s and the remainder at x_f .

Shooting method

How to solve a BVP using the shooting method:

- Define the system of ODEs
- Provide an initial guess for the unknown boundary condition
- Solve the system and compare the resulting boundary condition to the expected value
- Adjust the guessed boundary value, and solve again. Repeat until convergence.
 - Of course, you can subtract the expected value from the computed value at the boundary, and use a non-linear root finding method

BVP: example in Excel

Consider a chemical reaction in a liquid film layer of thickness δ :

$$\mathcal{D} \frac{d^2 c}{dx^2} = k_R c \quad \text{with} \quad \begin{array}{ll} c(x=0) = C_{A,i,L} = 1 & \text{(interface concentration)} \\ c(x=\delta) = 0 & \text{(bulk concentration)} \end{array}$$

Question: compute the concentration profile in the film layer.

Step 1: Define the system of ODEs

This second-order ODE can be rewritten as a system of first-order ODEs, if we define the flux q as:

$$q = -\mathcal{D} \frac{dc}{dx}$$

Now, we find:

$$\frac{dc}{dx} = -\frac{1}{\mathcal{D}} q$$

$$\frac{dq}{dx} = -k_R c$$

BVP: example in Excel

Consider a chemical reaction in a liquid film layer of thickness δ :

$$\mathcal{D} \frac{d^2 c}{dx^2} = k_R c \quad \text{with} \quad \begin{array}{ll} c(x=0) = C_{A,i,L} = 1 & \text{(interface concentration)} \\ c(x=\delta) = 0 & \text{(bulk concentration)} \end{array}$$

Question: compute the concentration profile in the film layer.

Step 2: Set the boundary conditions

The boundary conditions for the concentrations at $x = 0$ and $x = \delta$ are known.

The flux at the interface, however, is not known, and should be solved for.

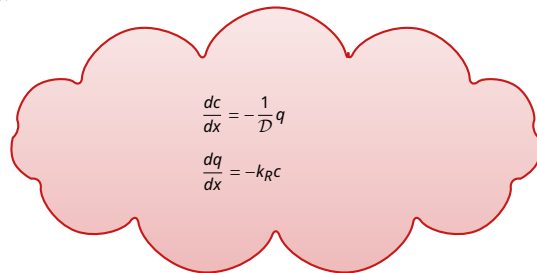

$$\frac{dc}{dx} = -\frac{1}{\mathcal{D}} q$$

$$\frac{dq}{dx} = -k_R c$$

BVP: example in Excel

Solving the two first-order ODEs in Excel. First, the cells with constants:

	A	B	C
1	CAiL	1	mol/m3
2	D	1e-8	m2/s
3	kR	10	1/s
4	delta	1e-4	m
5	N	100	
6	dx	=B4/B5	

$$\frac{dc}{dx} = -\frac{1}{D}q$$

$$\frac{dq}{dx} = -k_R c$$

Now, we program the forward Euler (explicit) schemes for c and q below:

	A	B	C
10	x	c	q
11	0	=B1	10
12	=A11+\$B\$6	=B11+\$B\$6*(-1/\$B\$2*C11)	=C11+\$B\$6*(-\$B\$3*B11)
13	=A12+\$B\$6	=B12+\$B\$6*(-1/\$B\$2*C12)	=C12+\$B\$6*(-\$B\$3*B12)
...
111	=A110+\$B\$6	=B110+\$B\$6*(-1/\$B\$2*C110)	=C110+\$B\$6*(-\$B\$3*B110)

BVP: example in Excel

- We now have profiles for c and q as a function of position x .
- The concentration $c(x = \delta)$ depends (eventually) on the boundary condition at the interface $q(x = 0)$
- We can use the solver to change $q(x = 0)$ such that the concentration at the bulk meets our requirement: $c(x = \delta) = 0$

BVP: example in Python

We first program the system of ODEs in a separate function:

$$\frac{dc}{dx} = -\frac{1}{D}q$$

$$\frac{dq}{dx} = -k_R c$$

```

1 # slides_example_bvp_1.py
2 def diffReactSystem(x, y, param):
3     c, q = y
4     f = np.zeros_like(y)
5     f[0] = -q/param['Diff']
6     f[1] = -param['kR']*c
7     return f

```

Note that we pass a variable (type: dictionary) that contains required parameters: `param`.

BVP: example in Python

Let's first try to solve the ODE system using `scipy.integrate.solve_ivp`:

```

1 # slides_example_bvp_1.py
2 import numpy as np
3 import matplotlib.pyplot as plt
4 from scipy.integrate import solve_ivp
5
6 ### Definition of diffReactSystem here (see slide 151 )
7
8 # Set up parameters
9 q0 = 1e-3 # Initial guess flux@t=0
10 param = {'cAiL': 1.0, 'Diff': 1e-8, 'kR': 10, 'delta': 1e-4, 'N': 100}
11
12 # Solve ODE system
13 sol = solve_ivp(lambda x, y: diffReactSystem(x, y, param), # ODE func with params
14                 [0, param['delta']], # Time span
15                 [param['cAiL'], q0]) # Initial conditions
16
17 fig, ax1 = plt.subplots()
18 ax1.plot(sol.t, sol.y[0, :], '-b', label='Concentration $mol/m^3$')
19 ax2 = ax1.twinx() # Create y-y axis
20 ax2.plot(sol.t, sol.y[1, :], '-r', label='Flux $mol/m^2/s$')
21 fig.legend(bbox_to_anchor=(0.5, 0.5))
22 plt.show()

```

BVP: example in Python

That seems to work! Now we want to fit the value for q at $x = 0$ (defined below as `bcq`), such that the concentration at $x = \delta$ equals zero. We create a function with the output defined as the deviation from the target value:

```

1 # slides_example_bvp_2.py
2 def diffReactFitCriterium(bcq, param):
3     # Solve the ODE system using changeable parameter bcq
4     # (boundary condition for q), other parameters are defined in param
5     sol = solve_ivp(lambda x, y: diffReactSystem(x, y, param), [0, param['delta']], [param['cAiL'], bcq])
6     # Return the last value of the concentration (column 0 in y) at x=delta (hence [-1])
7     return sol.y[0,-1] - 0

```

Note the following:

- We use the interval $0 \leq x \leq \delta$
- Boundary conditions are given as: $c(x = 0) = 1$ and $q(x = 0) = bcq$, which is given as a separate argument to the function (i.e. changable from 'outside!')
- The function returns the concentration at $x = \delta$

BVP: example in Python

Finally, we should solve the system so that we obtain the right boundary condition $q = bcq$ such that $c(x = \delta) = 0$. We can use the `scipy.optimize.root_scalar` function to do this. Extend the script from slide 152 by:

```

1 # slides_example_bvp_2.py
2 from scipy.optimize import root_scalar
3
4 ### Define diffReactSystem, diffReactFitCriterion, parameters
5
6 # Solve such that c(delta)=0:
7 sol = root_scalar(lambda x: diffReactFitCriterion(x, param),
8                   method='brentq', bracket=[0,1], xtol=1e-15, rtol=1e-15)
9 q0 = sol.root
10 print(f"{q0 = }")
11
12 # Solve ODE once more such that we can plot the final data
13 sol = solve_ivp(lambda x, y: diffReactSystem(x, y, param),
14                 [0, param['delta']], [param['cAil'], q0],
15                 t_eval = np.linspace(0, param['delta'], 101))

```

Postprocessing of the data can be done similar to the example in slide 152.

BVP example: analytical solution

Compare with the analytical solution:

$$q = k_L E_A C_{A,i,L} \quad \text{with}$$

$$E_A = \frac{\text{Ha}}{\tanh \text{Ha}} \quad \text{(Enhancement factor)}$$

$$\text{Ha} = \frac{\sqrt{k_R \mathcal{D}}}{k_L} \quad \text{(Hatta number)}$$

$$k_L = \frac{\mathcal{D}}{\delta} \quad \text{(mass transfer coefficient)}$$

Today's outline

● Introduction

- Backward Euler
- Implicit midpoint method

● Systems of ODEs

- Solution methods for systems of ODEs
- Solving systems of ODEs in Python
- Stiff systems of ODEs

● Boundary value problems

- Shooting method

● Conclusion

Other methods

Other explicit methods:

- Bulirsch-Stoer method (Richardson extrapolation + modified midpoint method)

Other implicit methods:

- Rosenbrock methods (higher order implicit Runge-Kutta methods)
- Predictor-corrector methods

Summary

- Several solution methods and their derivation were discussed:
 - Explicit solution methods: Euler, Improved Euler, Midpoint method, RK45
 - Implicit methods: Implicit Euler and Implicit midpoint method
 - A few examples of their spreadsheet implementation were shown
- We have paid attention to accuracy and instability, rate of convergence and step size
- Systems of ODEs can be solved by the same algorithms. Stiff problems should be treated with care.
- An example of solving ODEs with Python was demonstrated.
